**Abstract:** Lumbar epidural anaesthesia is one among the commonly performed regional anaesthesia especially for lower abdominal, lower limb surgeries and also for postoperative pain relief. Its ability to produce neuraxial blockade without dural puncture is an attractive option for spinal anaesthesia. To study the effect of alkalinization on the onset action of lignocaine in epidural anaesthesia. This study was done in ShaheedZiaur Rahman Medical College & Hospital, Bogura, Bangladesh in the year of 2018-19. After the institutional ethical committee approval and informed consent from the patient, 100 patients posted for lower abdominal surgery were selected after inclusion and exclusion criteria. The inclusion criteria were ASA I&II of both gender with an age group of 20-60 years and the exclusion criteria were age below 20years and above 60years, weight 45 to 85 kgs, spinal deformities, local sepsis, bleeding disorder and patient refusal. After the institutional ethical committee approval and informed consent from the patient, 100 patients posted for lower abdominal surgery were selected after inclusion and exclusion criteria and they were divided into two groups. Group S received Lignocaine with adrenaline added with Saline and Group A received alkalinized Lignocaine (with Sodium bicarbonate) with adrenaline. It was concluded that alkalinization shortens the onset of action of Lignocaine.

**Keywords:** Epidural anaesthesia, Alkalinization, Sodium bicarbonate, Saline, Lignocaine.

1. **INTRODUCTION**

Lumbar epidural anaesthesia is one among the commonly performed regional anaesthesia especially for lower abdominal, lower limb surgeries and also for postoperative pain relief. Its ability to produce neuraxial blockade without dural puncture is an attractive option for spinal anaesthesia [1-5]. Neural blockade follows when a local anesthetic is deposited in the vicinity of a nerve fiber. The onset of blockade occurs when the local anesthetic molecules reach the interior of the axoplasm in sufficient quantity. The drug molecule to reach the site of action, it has to travel many barriers especially in epidural anaesthesia and so, the onset of action is delayed [6]. By modifying the physicochemical properties, we can quicken the onset of action of local anesthetic. Sodium bicarbonate is one such adjuvant that alters the same.

1.1. **Aim of the Study**

To compare the effect of alkalinization on the onset of action of alkalinized and non-alkalinized Lignocaine.

2. **MATERIALS AND METHODS**

This study was done in ShaheedZiaur Rahman Medical College & Hospital, Bogura, Bangladesh in the year of 2018-19. After the institutional ethical committee approval and informed consent from the patient, 100 patients posted for lower abdominal surgery were selected after inclusion and exclusion criteria. The inclusion criteria were ASA I&II of both gender with an age group of 20-60 years and the exclusion criteria were age below 20years and above 60years, weight 45 to 85 kgs, spinal deformities, local sepsis, bleeding disorder and patient refusal. The patients were divided into two groups. Group S received Lignocaine with adrenaline added with Saline and Group A received alkalinized Lignocaine (with Sodium bicarbonate) with adrenaline. Epidual block performed with 18-G Tuohy's epidural needle in L3–L4 interspace by loss of resistance technique. Test dose of 3 ml of 2% lignocaine with adrenaline was injected followed by study drug 3 min later. Immediately after the injection, patients were placed in supine position.
All patients were monitored for the onset of anesthesia, effects on cardiovascular and respiratory parameters, and intra- and post-operative complications. Pulse rate, mean blood pressure, and SPO2 recorded after injection of local anesthetic at interval of 5, 15, 30, 60, 90, 120, and 150 min and more than 20% change as compared to preoperative values was considered significant.

2.1. Onset of Sensory Analgesia
Time from administration of drug to the time required for loss of touch sensation for an alcohol swab and loss of pinprick sensation at L2 level, which was judged at 1 min interval.

2.2. Method of Alkalization
0.8 ml of 8.4% Sodium bicarbonate was added with each 10 ml of 2% Lignocaine with the total of 20 ml. After the epidural space identification, the patients received the following drugs according to the group. All cases completed in stipulated time. Data were collected, compiled, and tabulated. All results were expressed as mean ± standard deviation. Two according to the drug received. The observations in the study are given as follows.

2.3. Demographic Data
There was not much significant variance in the each group.

3. RESULT
This study was a randomized double blind study, conducted on a total of 100 patients grouped into two according to the drug received. The observations in the study are given as follows. In group N, the lowest onset time was 5 minutes and longest onset was 14 minutes with a mean of 7.87±1.834 (standard deviation). In group A, the, lowest onset of time was 1 minute and longest onset of time was 5 minutes with a mean of 2.665±0.994 (standard deviation).

4. DISCUSSION
The pH of the local anesthetic solution immediately before injection to raise the pH. This is called alkalization of the solution. Anesthetic activity is dependent on having both the ionized and nonionized forms of the drug present after injection. Alkalization increases the proportion of non-ionized drug and this could be advantageous. Care must be taken, because if too much alkali is added and mixing of any other drug, the local anesthetic will get precipitated. Local anesthetics are the basic
drugs which have a pKa close to the normal extracellular pH of 7.4, for example lignocaine has a pKa of 7.8. The drugs exist in two forms in the solution – the uncharged basic form (B) and the charged form (BH). B + H+ ↔ BH. The importance of the pKa-pH relationship is that this knowledge allows the calculation of the relative amounts of these two forms. When the pH is equal to the drug's pKa, 50% of the drug is in the uncharged form, and 50% is in the charged form. In acidic solutions, most of the drug will be in the charged form. When injected, the local anesthetic solution must be present in the tissues in both forms. The reason is that the drug has to diffuse to the site of action across several tissue barriers. The uncharged lipid-soluble form will diffuse across lipid barriers, for example, perineural sheath, or cell membrane. The charged water soluble form will diffuse across tissue fluid barriers, for example interstitial fluid. The site of action of the local anesthetic molecule is the inner (or cytoplasmic) end of the sodium channel in the cell membrane. The final pathway for all injected local anesthetics is to diffuse to the cell membrane (in the charged form) then reequilibrate to form both charged and uncharged forms adjacent to the outside of the nerve cell membrane. The molecules diffuse across the nerve cell membrane in the uncharged form and then re-equilibrate in the cytoplasm to have both forms present again. Next the charged form diffuses to and binds to its receptor on the inside of the transmembrane sodium channel. This binding results in a conformational change in the channel protein to block the passage of sodium ions into the cell in response to a subsequent action potential. Onset of sensory block was significantly quicker in alkalinized group. Our observation was similar to observation by many authors [1-13]. Addition of bicarbonate for increasing pH of local anesthetic in epidural blockade hastens the onset of action by increasing the pH of the solution and thereby it increases the uncharged base form available for penetration. Our result is similar to Aparna Abhijit Bagle et al. [11]. For epidural anaesthesia, time to achieve surgical anaesthesia is important. Onset of epidural anaesthesia was quicker with alkalinized local anaesthetic solutions, but only by a few minutes. Dr.P.Chalapathy et al. concluded alkalinized lignocaine hydrochloride solution provides a significant advantage over non alkalinized lignocaine hydrochloride in terms of quicker onset, duration and quality of block [13]. Cardiovascular stability was found in all groups which is the feature of epidural analgesia and there was no incidence of postoperative complications in any of the group in our study.

5. CONCLUSION

It was concluded that alkalinization shortens the onset of action of Lignocaine. We conclude that pH-adjusted 1% lidocaine offers the advantage of a more rapid onset of sensory blockade, while motor blockade and the distribution of anesthesia are unaffected by pH change in epidural anesthesia.
