**Summary:** Cryptosporidiosis is the worldwide zoonotic disease caused by protozoan parasite of the genus Cryptosporidium which infects the micro-villous border of the gastrointestinal and respiratory epithelium of wide range of vertebrates including human beings and causing diarrhea in both immune-competent and immune-compromised individuals. It follows monoxenous life cycle which requires single host and grow only in living cells but can survive in the environment for long periods without losing its infectivity. Its transmission occurs through direct or indirect contact with feces of infected animals or humans whereas a contaminated food and water are source infection. Age, immune status, concurrent infection and resistance of the parasite to adverse environmental factors are the risk to factors associated with cryptosporidium infection. It’s diagnosis of is mainly based on identification of oocysts from fecal materials while species identification rely on molecular techniques. Cryptosporidium causes high morbidity which results in production losses and death of live animals in the different countries of the world. Additionally, it accounts for up to 20% of all cases of childhood diarrhea in developing countries. Furthermore, it is a potentially fatal complication of AIDS. Since, it’s highly resistance to antimicrobials and anticoccidials no effective therapeutic agent is available to date. Nevertheless, halofuginone lactate and nitazoxanide are being used for pro- and metaphylaxis treatment. As a result, good hygiene measures are important to control and prevent the disease. Moreover, comprehensive documented materials on cryptosporidium and its public health importance are scarce. Therefore, well compiled papers are needed for better understanding, effective treatment and implementation of sound prevention and control measures.

**Keywords:** Cryptosporidium, Protozoa, zoonotic, Parasite

1. INTRODUCTION

Cryptosporidiosis is the worldwide disease caused by protozoan parasite of the genus Cryptosporidium, which was discovered in 1910 by Edward Ernst Tyzzer in the gastric glands of mice and he named it from the Greece word ‘kruptos” meaning ‘hidden as it did not contain sporocysts within the oocysts and it sporulates while still attached to the host wall (Tyzzer, 1910). Cryptosporidium is an intracellular protozoan parasite that associated with gastrointestinal diseases with a wide host range affecting all classes of vertebrates including mammals, reptiles, birds and fish (Kosek et al, 2001; Chen et al., 2002). It is protected by an outer shell that allows it to survive outside the body for long periods of time and makes it very resistant to chlorine disinfectants (Kosek et al, 2001). As a result, the oocysts of the Cryptosporidium can survive for several months and retain infectivity in a latent form outside the host, despite adverse environmental factors, including salinity and chemicals (Sunnotel et al., 2006; Smith et al., 2007).

Cryptosporidium is monoxenous life cycle that causes diarrhea in immunocompromised individuals and neonates that believed as resulted from parasite invasion and epithelial destruction with the result of mild to moderate villus atrophy and microvillii shortening and destruction (deGraaf et al., 1999). Cryptosporidium oocysts are transmitted between hosts via the fecal-oral route, either directly from contact with faeces of infected animals or indirectly through environmental contamination or from ingestion of contaminated food or water whereas; age, immune status, concurrent infections, management and hygienic condition are the potential risk factors (Thomson, 2014).
Diagnosis of cryptosporidiosis is traditionally based on the detection of fecal oocysts by fecal flotation but immunofluorescent assay visualization of oocysts is currently being used as diagnostic techniques in most clinical laboratories while Molecular technique like PCR required for species identification (Fayer and Xiao, 2008). Regarding its treatment, there is not guarantee for an effective treatment in both human and veterinary medicine. However; Nitazoxanide and Halofuginone are approved drugs for pro- and metaphylaxis treatment respectively (Shahiduzzaman and Daugschies, 2012).

Control of cryptosporidiosis has to rely on reducing the prevalence of the parasite and on breaking the transmission pathways of Cryptosporidium species causing disease in animals, transmitting them to humans (zoonotic) or those perpetuating infection in humans only (anthroponotic). However, such a documented information to initiate studies and planning of control measures is limited or totally absent in many countries of the world (Yosra, 2014). Similarly, in Ethiopia, despite it has been reported cryptosporidium infection is highly prevalent; there was scarcity of well documented information regarding economical and public health importance of this zoonotic parasite. Therefore, the objective of this review paper is:

- To review available information on *cryptosporidium* and its public health importance

2. LITERATURE REVIEW

- Etiology and Taxonomy

The taxonomic status of the genus Cryptosporidium remains enigmatic; the speciation of the genus continues to be a challenge to taxonomists. Traditionally, Cryptosporidia was considered as protozoan parasites due to great similarities and are classified in the Coccidia class of the phylum Apicomplexa, although Cryptosporidia show features which differ them from all other Coccidia and concluded a closer affinity of Cryptosporidia with the gregarines (Apicomplexa: Gregarinasina) (Hijjawi et al., 2002). Similarly, Xiano et al. (2004), taxonomic studies place Cryptosporidium as a clade separate from the coccidian it invades the microvillus border of GIT and respiratory epithelium of a wide range of vertebrate animals and is associated with watery diarrhea in mammals, diarrhea and respiratory illness in birds and gastroenteritis in reptiles and fish. In addition, coccidian species are generally named based on unique oocyst morphology, but within the *Cryptosporidium* genus several species have similar oocyst morphology (Fayer, 2008). However, recent whole genome comparisons by Templeton et al. (2010), suggested that Cryptosporidium is neither coccidian nor gregarine. Therefore, Cryptosporidium may have its own separate lineage is likely to reveal new avenues of investigation into pathogenesis, epidemiology, treatment and control of these ubiquitous pathogens (Barta and Thompson, 2006).

- Life Cycle of Cryptosporidium

*Cryptosporidium* is a monoxenous organism, life cycle completed within a single host, which can be divided into an asexual (sporogony and schizogony/merogony) and a sexual (gamogony) phase (Fujino et al., 2002). The exogenous stage of the *Cryptosporidium* life cycle is a sporulated, thick walled oocyst which is excreted in the faeces of an infected host. However, the endogenous part of the life cycle begins when the infectious oocysts are ingested either via contaminated water or feed. In the gastrointestinal lumen the oocyst will release sporozoites, which parasitize the villous enterocytes. The developing stages remain at the luminal surface of the enterocytes. But they are covered by the plasma membrane of the host cell. Thus they are spoken of as being intracellular but extracytoplasmic. The sporozoites differentiate, intracellularly, into trophozoites (unicnucleate meronts) that undergo asexual multiplication by nuclear division leaving behind type I and type II meronts. Type I meronts produce six to eight merozoites, which in turn invade epithelium cells and form type II meront. Type I merozoites can either go to a type II meront or return to form another generation of type I. The type II meront produces merozoites. They will initiate sexual multiplication as they differentiate into either male micro-gamonts or female macro-gamonts (Rimhanen-Finne, 2006). The fertilized macrogametes develop into thick walled oocyst, which are excreted from the body or into thin walled oocysts. The later is responsible for repeated asexual and sexual multiplication (autoinfection) within the same host (KHIN, 2007).
The prepatent period in experimental or accidental infections with the different Cryptosporidium species varies from 2 to 14 days in various animal hosts and from 5 to 28 days in humans. The patent period in domestic and companion animals vary from one day to two to four weeks. Two morphological different species of Cryptosporidium are identified in cattle. The first, found in the small intestine, is C. parvum and the second, the stomach infecting larger species, are named C. andersoni (Lindsay et al., 2000). As the morphology, the molecular markers and the experimental infectivity of those two species vary, their prevalence also varies in relation to the age of the calves and to the housing technology (Santin et al., 2004). In addition to those dominant species multiple, less-closely related genotypes are also known. Some of these genotypes acquired a species name and many await further biological characterization (Xiao, 2004). Most recently, a species from cattle, C. bovis (formerly known as ‘bovine B genotype’), and a ‘deer-like genotype’ are identified (Santin et al., 2004). Both of these genotypes are biologically and genetically distinct from dominant species of C. hominis, C. parvum, bovine genotype and C. wrairi (Slapeta, 2007).

- **Epidemiology**
- **Geographical Distribution**

Cryptosporidiosis has been recognized worldwide, primarily in neonatal calves, but also in lambs, goat kids, foals, and piglets. Many studies report prevalence of infection but this does not imply clinical disease (Radostits et al., 2006). In humans, the application of PCR assays to identify Cryptosporidium species from stool samples has shown that C. hominis and C. parvum are the major causes of human cryptosporidiosis (Cacciò, 2005). However; the prevalence of these species varies in different regions of the world. C. hominis is by far more prevalent in North and South America, Australia and Africa, while C. parvum causes more human infections in Europe, especially in the UK (Figure 2). Geographic variation occurs also within a country (McLauchlin et al., 2000) and molecular epidemiological studies indicate that the proportion of C. parvum infections in humans is much higher in rural than in urban areas (Learmonth et al., 2004).

- **Host Range**

In animals, it was found that different species of *Cryptosporidium* infect farm animals while fish, poultry, amphibians and reptiles are also susceptible (Thomson, 2016). Once *Cryptosporidium* was considered to cause opportunistic infection, but now, together with enterotoxic *Escherichia coli* (ETEC) and Rota- and Corona-viruses, it is an important component of the calf diarrhea complex (Gulliksen et al., 2009). Currently, 26 morphologically, biologically and molecular-biologically confirmed different *Cryptosporidium* species are listed (Fayer and Santin, 2009; Elwin et al., 2012; Lebbad et al., 2013; Adamu et al., 2014), having mammals (primates, bovidae, equidae, carnivora, hares, rabbits, tapiridae and rhinocerotidae), amphibians, reptiles and birds as hosts. Major species found in mammals are: *C. andersoni*, *C. bovis*, *C. canis*, *C. fayeri*, *C. felis*, *C. hominis*, *C. macropodum*, *C. muris*, *C. parvum*, *C. ryanae*, *C. suis* and *C. wrairi*. The three originally from birds isolated species are *C. baileyi*, *C. galli* and *C. meleagridis*, whereas *C. serpentis*, and *C. varanii* originate from reptiles and *C. fragile* from amphibians (Fayer, 2008).

- **Cattle**

There are four species of Cryptosporidium which are commonly found in cattle; *C. parvum*, *C. bovis*, *C. ryanae* and *C. andersoni*. There are some reports of other species also being found; *C. hominis* has been reported in a three day old calf and a six year old cow from Scotland (Smith et al., 2005), *C. suis* in a calf (Fayer et al., 2006) and *C. felis* in a cow (Bornay-Llinares et al., 199).

- **Sheep and goats**

Sheep and goats are predominantly infected with *C. parvum*, *C. xiaoai*, *C. bovis* and *C. ubiquitum* although rare occurrences of other species have been reported. *Cryptosporidium hominis* has been reported as the predominant species in sheep on the Scottish island of St Kilda (Connelly et al., 2013), in a sheep and a goat kid from a farm and petting zoo in the UK (Giles et al., 2009) and in a sheep in Australia (Ryan et al., 2005). *Cryptosporidium scruorum* and *C. andersoni* have been detected in sheep from flocks in Australia (Yang et al., 2014) and *C. fayeri* has been reported in a sheep (Ryan et al., 2005) again these occurrences of other species are rare.

- **Pigs**

The predominant species of *Cryptosporidium* detected in pigs are *C. suis* and *C. scruorum*; *C. suis* is prevalent in pigs worldwide but causes few clinical signs (Enemark et al., 2003). *Cryptosporidium*
Cryptosporidium and Its Public Health Importance: Review

*Cryptosporidium* is a fairly new species, only described in 2013 (Kvac *et al*., 2013), again, this species does not seem to cause any clinical disease in pigs yet is prevalent in adult pigs worldwide. It does not appear infective to pigs under eight weeks of age (Kvac *et al*., 2014).

- **Poultry**

Three species of *Cryptosporidium* are currently known to infect birds; *C. meleagris*, *C. baileyi* and *C. galli*. Avian cryptosporidiosis was first described in 1929 but was not formally recognised until 1955 when *C. meleagris* was reported in turkeys (Sarah, 2016). *C. meleagris* is found in the small and large intestine and bursa of infected birds. *Cryptosporidium meleagris* has been reported in many different species of birds and also in humans (Silverlas *et al*., 2012; Ng-Hublin *et al*., 2013; Wang *et al*., 2014). The second species of Cryptosporidium to be reported in birds was *C. baileyi* in chicken in 1986 (Current *et al*., 1986), this species is more commonly associated with respiratory cryptosporidiosis in broiler chickens and is the most common species of avian Cryptosporidium. Also described from chickens is *C. galli* which was discovered in 1999 but was redescribed in 2003 (Ryan *et al*., 2003). Like *C. meleagris* this species is also found in the small intestine, large intestine and in the epithelium of the proventriculus and is associated with clinical disease and mortality (Tunova *et al*., 2002). The three avian adapted species are morphologically different and can be distinguished by morphological difference in the size and shape of the oocysts (Sarah, 2016).

- **Fish**

In fish three species have been reported but it is possible that there are more which remain undiscovered as studies into the species of Cryptosporidium found in fish are scarce. The first species in fish to be described was *C. molnari* infecting the stomach of giltthead sea bream and European sea bass with few clinical signs (Alvarez-Pellitero and Sitja-Bobadilla, 2002). The other reported species of Cryptosporidium infecting fish is *C. scophthalmi* which is found in the intestinal epithelium of turbot (Thomson, 2016).

- **Amphibians and reptiles**

Four species of Cryptosporidium have been reported in amphibians and reptiles, *C. fragile*, *C. varanii*, *C. serpentis* and *C. duisenmarci*. As its name suggests, *C. fragile* is the most delicate species of *Cryptosporidium* and was first described in the stomach of the black-spined toad (Jirku *et al*., 2008) and was named due to its fragile nature. Unlike other species of *Cryptosporidium*, *C. fragile* will crumple on contact with hypertonic solutions and disintegrate after just 4 weeks in water (Thomson, 2016). *Cryptosporidium* has been reported in many species of snakes and other reptiles, the first to be identified was *C. serpentis* which is a gastric species and was found in four snake species in 1977 (Brownstein *et al*., 1977).

- **Human**

In humans there are two species which are routinely diagnosed in clinical cases of cryptosporidiosis; these are the zoonotic species *C. parvum* and the human adapted species *C. hominis* (Morgan-Ryan *et al*., 2002). Cryptosporidiosis is highly dependent on the immune status of the host and thus, immunocompromised individuals can develop a chronic and life-threatening diarrheal disease while immunocompetent individuals most commonly develop acute self-limiting gastroenteritis. Due to their immature immune status, children are highly susceptible for infections with *Cryptosporidium* and routinely get infected by oral uptake of even low infective doses of the parasite’s oocysts. It was estimated that 1 to 10% of the populations in developing countries were infected with *Cryptosporidium*, wherein 1-to-9-year-old children and toddlers were the most affected groups (Chen *et al*., 2003). Moreover, the intestinal malabsorption caused by cryptosporidiosis in developing countries further affects particularly malnourished children (Desai *et al*., 2012).

A true host specificity of the species in most cases, however, does not exist and after *C. baileyi*, *C. canis*, *C. felis*, *C. meleagris*, *C. bovis*, *C. suis*, *C. andersoni* and *C. muris* also were detected in cases of human cryptosporidiosis, these species, further to *C. parvum*, also have to be considered potentially zoonotic (Helmy *et al*., 2013). The zoonotic potential of these species has to be judged as lower, although not in immunosuppressed persons (Lendner *et al*., 2011).

*Cryptosporidium parvum* (*C. parvum*) infects a number of mammalian hosts whereas *C. hominis* infects only humans (Leav *et al*., 2003). Despite their identical morphology, the two species can be
Cryptosporidium and Its Public Health Importance: Review

distinguished by molecular methods. Some studies have also shown a lot of heterogeneity among the genotype 1 (C. hominis) isolates. The heterogeneity is seen at the Cpgp40/15 (also known as gp60/45/15) locus which encodes for surface glycoproteins present during the invasive stages of the parasite (Strong et al., 2000).

- Transmission and Source of Cryptosporidium

Cryptosporidium oocysts are transmitted between hosts via the fecal-oral route, either directly from contact with faeces of infected animals or indirectly through environmental contamination or from ingestion of contaminated food or water. Transmission is by the faecal-oral route and may involve a vehicle such as contaminated food or drinking water. Calves usually become infected by the oral uptake of oocysts from the environment. Possible major sources of infection, next to infected and shedding neighbor animals, are contaminated stables, faeces and dirty teats and udders of suckling cows (Yosra, 2014).

Cryptosporidium parvum is highly infectious for young livestock and humans; older livestock can remain infected and excrete oocysts that can be transmitted to other susceptible hosts. Oocysts can survive for long periods (>6 months) in cool, moist environments, and on fomites such as farm gates, buildings and utensils. Oocysts can be transmitted following direct contact with faeces from an infected individual, or contact with contaminated fomites, or by ingestion of contaminated food or water. Transmission of C. hominis is considered to be anthroponotic (Flores and Okhuysen, 2009; Borad and Ward 2010; Yang et al., 2010). Impact of water livestock on transmission is waterborne contamination is a growing concern causing widespread disease outbreaks. Factors that have contributed to the emergence of cryptosporidiosis in animals include increased environmental contamination and trends in livestock production (Borad and Ward, 2010).

In humans the zoonotic nature of infection, along with increased numbers of at-risk population have contributed to the rate intensification of the disease (Mosier and Oberst, 2000). There are some reports of veterinary students, typically from urban areas, becoming infected with C. parvum when they start...
working with farm livestock (usually calves) during their studies (Preiser et al., 2003; Gait et al., 2008) as well as outbreaks amongst members of the public associated with petting zoos or farm visits (Gormley et al., 2011). Cryptosporidium can be transmitted from animals to humans through direct contact. This has occurred with veterinary workers (Preiser, 2003) and other people exposed to animals (Stantic-Pavlinic, 2003), particularly farm workers (Mahdi and Ali, 2002), and in animal nursery fair (Ashbolt, 2003). Retrospective analysis of samples collected at the time of the outbreak has infected hosts can shed huge numbers of oocysts per day, which are immediately infective to other susceptible hosts meaning that infection can pass very quickly between animals kept in close contact to one another (Nydam et al., 2001; Zambriski et al., 2013).

Risk Factors

The factors that make animals susceptible to infection and that predispose infected animals to develop clinical disease are not well understood. Disease in agricultural animals associated with infection with Cryptosporidium is associated with infection with C. parvum and there is little evidence that infection with C. andersoni is associated with disease. Commonly, other enteric infections are present where there is disease attributed to Cryptosporidium. The site of infection with C. parvum is on the enterocyte where it results in cell damage, loss of brush border enzymes and a reduction of villous surface area (Radostits et al., 2006).

Age

There is a significant association between age and risk of infection with Cryptosporidium. Cryptosporidiosis due to C. parvum is predominantly a problem of neonate animals with maximum rate of excretion of oocysts between the age of 4 and 21 days. According to Huetink et al. (2001); Xiao et al. (2004) and Nguyen et al. (2007), age appeared to be an important factor that influences the occurrence of the Cryptosporidium. The calves under 3 months are at higher risk of infection compared to the older ones. The higher prevalence in this age group can be attributed to the fact that these age groups are highly susceptible to the disease because of the immature immune system of the animal at this age (Regassa, A., 2009). Kvac et al., (2006) explained that the animal is becoming resistant with age due to the immune development through time.

Although exceptions occur, older animals generally develop poor infections, even when unexposed previously to this parasite (Xiao et al., 2004) age-related resistance, unrelated to prior exposure, has been observed in lambs but not calves (Radostits et al., 2006). The common occurrence of cryptosporidiosis in young animals reflects their susceptibility to infection with a low number of oocysts and common exposure to oocysts (Fayer, R. and L. Xiao, 2008).

Pathogen risk factors

Oocysts are resistant to most disinfectants and can reportedly remain viable for about 18 months in a cool, damp or wet environment, can survive for several months in soil and slurry, but are susceptible to desiccation and temperatures above 60°C. The infectivity of the oocysts can be destroyed by ammonia, formalin, freeze-drying and exposure to temperatures below 0°C (32°F) and above 65°C (149°F). Ammonium hydroxide, hydrogen peroxide, chlorine dioxide, 10% formol saline and 5% ammonia are effective in destroying the infectivity of the oocysts. The infectivity of oocysts in calf feces is reduced after 1-4 days of drying (Radostits et al., 2006).

Concurrent infections

Concurrent infections with other enteropathogens, especially rotavirus and coronavirus, are common and epidemiological investigation suggest that diarrhea is more severe with mixed infections. Mixed infections are most common, but cryptosporidia infection can be significant in its own right. Immunologically compromised animals are more susceptible to clinical disease than immunocompetent animals, but the relationship between disease and failure of passive transfer of collostral immunoglobulins is not clear. The disease can be reproduced in both colostrum-deprived and colostrum fed calves and, in the field, clinical disease can occur in calves and foals with adequate passive transfer of collostral immunoglobulins. However, the shedding of the organism has been observed to be higher in calves with low absorptive efficiency of IgG from colostrum and low serum IgG concentrations (Radostits et al., 2006).

Immune Status

Undeveloped immune systems are The usually seen in young livestock and human infants Weakened immune systems may be seen in animals suffering from other diseases, elderly humans and
Cryptosporidium and Its Public Health Importance: Review

malnourished persons; individual’s receiving chemotherapy or corticosteroid therapy and HIV positive individuals(Suleiman and Xiao, 2001). These individuals experiences increased mortality, decreased weight gain or weight loss and generally poorer performance overall when compared to healthy animals. Additionally, infected animals represent a potentially large source of oocysts that can contaminate water and foods used for human consumption. A single infected calf can excrete up to 10 billion oocysts during a 2 weeks infection (Douglas, 1999).

• Morbidity and Mortality

Cryptosporidium is the cause of diarrhea in man and one of the more common opportunistic pathogen affecting human patient with AIDS. High morbidity which results in production losses and death of live animals from its high mortality specially, in calves and immunocompromised individuals are significant problems to farm owners (Thomson, 2014). Morbidity and Mortality in North America, approximately 2% of the population is infected and 80% has been exposed at some time. Worldwide; the prevalence is 1 to 4.5% in developed countries and 3 to 20% in developing countries. In healthy people the infection is usually self-limiting and resolves after 2 to 4 days; however, episodes of diarrhea lasting 1 to 4 weeks have been seen at some day care centers. Cryptosporidiosis infections may develop in immunosuppressed individuals, particularly AIDS patients; these infections may be debilitating and contribute to death. Estimated infection rates in AIDS patients range from 3 to 20% in the United States and 50 to 60% in Africa and Haiti (CFSPH, 2005).

• Pathogenesis

Calves usually become infected with Cryptosporidium between the age of one to four weeks and the duration of disease is short; it lasts maximally up to two weeks (Fayer et al., 2000; Ralston et al., 2003). Calves begin shedding oocysts as early as in the age of two days. The peak shedding occurs with 14 days of age (Olson et al., 2004). The pathogenesis of Cryptosporidium induced diarrhea is believed to result from parasite invasion and epithelial destruction with the result of mild to moderate villus atrophy and microvillii shortening and destruction (deGraaf et al., 1999). This will lead to impaired nutrient absorption and transport. The main clinical manifestations of C. parvum in cattle are diarrhea, depression, anorexia and abdominal pain (Ralston et al., 2003; Fayer et al. 2000). In general clinical cryptosporidiosis is observed in calves of the age of 7–30 days. It lasts 4–14 days. The severity and duration are highly variable among calves (Olson et al., 2004). The diarrhea, which is pale yellow with mucus, can be mild to severe and can last up to two weeks resulting in lethargic, anorexic and dehydrated calves. In severe cases, calves die from dehydration and cardiovascular collapse. Other enteric viral, bacterial and parasitic pathogens such as Rotavirus, Escherichia coli and coccidia could also be observed in calves during the first four weeks of life. This exaggerates the severity of cryptosporidiosis (Joachim et al., 2003). Calves with severe cryptosporidiosis take four to six weeks to fully recover which causes an initial negative impact on the production (Ralston et al., 2003).

• Clinical Signs

There is no clinical findings characteristic of diarrhea due to infection with C. parvum in calves. In general, calves are usually 5-15 days old and have a mild to moderate diarrhea which persists for several days regardless of treatment. The age at onset is later, and the duration of diarrhea tends to be a few days longer, than the diarrheas associated with rotavirus, coronavirus, or enterotoxigenic Escherichia coli. The persistent diarrhea results in marked loss of body weight and emaciation in some cases. In most cases, the diarrhea is self-limiting after several days. Varying degrees of apathy, reduced feed intake and dehydration are present. Only rarely does severe dehydration, weakness and collapse occur, in contrast to other causes of acute diarrhea in neonatal calves drying (Radostitis et al., 2006). The clinical symptoms of Cryptosporidium differ between non-immunocompromised and immunocompromised individuals. In non immunocompromised individuals, the disease is usually a self-limiting acute gastroenteritis, characterized by vomiting, weight loss, fever, watery diarrhoea, cramping, abdominal pains, flatulence, malaise and myalgia (Chin, 2000).

In animals, cryptosporidiosis is mainly observed in young calves and the severity of the disease depends on several factors such as host immunity, infective dose and current infection with other pathogens such as rotaviruses. Symptoms vary from asymptomatic to pasty or watery profuse diarrhea, dehydration and mortality. C. parvum, together with enterotoxigenic Escherichia coli and Rota-
Cryptosporidium and Its Public Health Importance: Review

and Corona-viruses, is an essential component of the calf diarrhea complex (diarrhea within the first three weeks) and by this is one of the major causes of losses in calf rearing (Yosra, 2014).

The clinical picture of the neonatal diarrhea within a mono- or also mixed-infection with *C. parvum* is characterized by profuse, yellowish diarrhea and its consequences, like exsiccosis, metabolic acidosis and loss of electrolytes (Kaske et al., 2008). These become manifest in form of caved in bulbi, decreased skin turgor, coolish acra and general infirmity. Case fatality rates can be high in herds with cryptosporidiosis when the calf feeder withholds milk and feeds only electrolyte solutions during the episode of diarrhea. The persistent nature of the diarrhea leads to a marked energy deficit in these circumstances and the calves die of inanition at 3–4 weeks of life. This syndrome may be particularly common in the winter months where there is additional cold stress affecting energy requirements. Feed intake is reduced and, combined with the persistent diarrhea over several days, may cause emaciation. Recovery occurs between 6 and 10 days after the onset of diarrhea (Radostits et al., 2006).

**• Diagnosis**

Diagnosis of cryptosporidiosis is traditionally based on the detection of fecal oocysts. The oocysts can be detected in the feces by examination of fecal smears with certain stains, by fecal flotation, or by immunologically assisted methods. Current diagnostic techniques used in most clinical laboratories include the immunofluorescent assay visualization of fecal oocysts. It has been suggested that, if the diarrhea is associated with cryptosporidia, the feces should contain 105–107 oocysts per mL of feces (Radostits et al., 2008).

**• Parasitological diagnosis**

Several methods exist to detect *Cryptosporidium* in fecal samples. Among them the most common method is microscopy for the detection of oocysts. Fecal samples can be examined directly on slides or after concentration either by flotation or sedimentation to remove fecal debris or to concentrate the number of oocysts; the detection of oocysts in animals with low numbers of oocysts is facilitated (Fayer and Xiao, 2007). Visualization of *Cryptosporidium* oocysts by microscopy most commonly done by direct smear and without any staining and by the modified Ziehl-Neelsen stain under light microscopy, whereby the oocysts stain purple with blue background. Immunofluorescence staining techniques using monoclonal antibodies against the oocyst wall antigen under epifluorescence microscopy are also useful. Immunofluorescent antibody-based (IFA) procedures have a high sensitivity, but still the easier and cheaper traditional staining methods such as the Ziehl-Neelsen stain are widely used, despite their lower sensitivity (Caccio and Widmer, 2014). Most parasitological detection methods for *Cryptosporidium* do not distinguish between viable and nonviable oocysts (Yosra, 2014).

**• Serological diagnosis**

Serological methods are particularly useful tools for screening of large numbers of samples, like in epidemiological surveys. Most serological tests used to identify exposure/infection are enzyme linked immunosorbent assays (ELISA) or enzyme-linked immunoelctrotransfer blots (EITB; Western blot) employing various aqueous extracts of *C. parvum* oocysts (Yosra, 2014). Enzyme immunoassay (EIA) methods are fast, inexpensive, easy to be performed, and show sensitivity comparable to that of the immunofluorescence methods (Fayer and Xiao, 2007). Rapid immunochromatographic (strip) tests can be also used. These tests rely on the detection of cell wall proteins of the oocysts using monoclonal antibodies (Papini and Cardini, 2006).

**• Molecular detection of Cryptosporidium**

Several nucleic acid detection techniques are described for the detection of *Cryptosporidium*, some of which may be able to distinguish viable from nonviable oocysts (Egyed et al., 2002). Species differentiation using molecular methods can be done in a few different ways; these begin with DNA extraction from oocysts and PCR amplification of the gene(s) of interest. DNA extracted from oocysts can be amplified using standard or nested PCR methods. This is useful if the sample only contains a small amount of DNA as it results in more DNA copies than standard PCR. Species can be differentiated using restriction enzymes to digest PCR products into fragments of different sizes (PCR Restriction Fragment Length Polymorphism (RFLP)) and these fragments can be visualised on the agarose gel, producing varying banding patterns depending on species (Sulaiman et al., 1999).
Another PCR method which can be used to detect and speciate Cryptosporidium parasites is real-time PCR which is considered to be the “gold-standard” for Cryptosporidium detection as this method is the most sensitive and can detect as few as 2 oocysts per PCR (Hadfield et al., 2011). In real-time PCR the amplification of the DNA can be tracked in “real time” and the amount of DNA present can be quantified, this is an advantage over standard PCR which can only indicate the presence of parasite DNA but cannot quantify the amount (Chalmers et al., 2011).

### Differential Diagnosis of Cryptosporidium

The differential diagnosis for Cryptosporidium includes other entero-pathogens involved in diarrhoea. Multiple pathogens can be present including other parasites, rotavirus, coronavirus, pathogenic strains of E. coli and Salmonella spp. Cryptosporidiosis in livestock is confirmed by finding significant numbers of oocysts in diarrhoeic faeces in the absence of other pathogens, and although it has been widely speculated that co-infection may lead to more severe cryptosporidiosis (Lorenz et al., 2011) but experimental data to support this are lacking.

A differential diagnosis list for cryptosporidiosis includes Giardia, Isospora, microsporidia, Salmonella, rotavirus and other diarrheal diseases. Cryptosporidiosis can be diagnosed by finding C. parvum after a fecal flotation in either sucrose or zinc sulfate solutions. The mature oocysts are 4-5 μm in diameter and contain four thin, flat, motile sporozoites. Cryptosporidium parvum can also be detected through an acid-fast staining. Oocysts are not shed continuously and repeated sampling may be necessary. The oocysts appear red after the staining. Immunofluorescence can also be used to detect Cryptosporidium in feces. Finally, cryptosporidiosis can be detected by stained biopsy/necropsy specimens or fresh intestinal scrapings (CFSP H, 2011).

### Therapeutics

At present there are very few products licensed in the treatment or prevention of cryptosporidiosis in livestock or humans, the few products which are available are not very effective and in most cases will only reduce the duration of shedding and have little or no effect on immunocompromised patients. The only licensed treatment for cryptosporidiosis in calves is halofuginone lactate which affects invading parasite stages of Cryptosporidium (Jarvie et al., 2005). This drug is approved for use in both prevention and treatment of cryptosporidiosis in calves at a dose of 0.10 mg/kg of body weight per day for seven consecutive days. As a preventative measure the drug should be given within 48 hours of birth and as a therapeutic, within 24 hours of the onset of symptoms. Treatment with halofuginone lactate does not completely prevent or cure disease but it does reduce oocyst shedding and duration of diarrhoea (Jarvie et al., 2005; Trotz-Williams et al., 2011). But there is no licensed treatment for cryptosporidiosis in sheep, goats or pigs (Viu et al., 2000). However, a few coccidiostats, such as decoquinate have been tested against Cryptosporidium with limited or no reduction in oocyst shedding (Moore et al., 2003).

In human, Nitazoxanide, a nitrothiazolylsalicylamide was approved for the treatment of cryptosporidiosis. The efficacy of Nitazoxanide without an efficient immune system (number of CD4 cells) seems to be limited; several authors therefore only at test a partial efficiency (Cabada and White, 2010).

### Supportive therapy

Affected calves should be supported with fluids and electrolytes, both orally and parenterally as necessary until spontaneous recovery occurs. Cows' whole milk should be given in small quantities several times daily to optimize digestion and to minimize loss of body weight. It is important to continue to feed milk to the full level of requirement despite the presence of diarrhea, as a reduction in intake may lead to death from inanition. Several days of intensive care and feeding may be required before recovery is apparent. Parenteral nutrition could be considered for valuable calves (Radostits et al., 2006).

### Control and Prevention

Cryptosporidium organisms are common in the environment and can be carried by animals without any symptoms. Keeping sick animals away from the healthy animals is a good way to limit exposure. Chlorine does not effectively kill the organism and it is resistant to many disinfectants. Clean and disinfectant (5% ammonia solution can work) areas where sick animals have been or had diarrhea.
Also, provide good nutrition to the animals and keep the animals healthy to minimize the risks (Radostits et al., 2008).

Cryptosporidiosis is a difficult disease to control, as the oocysts are very environmentally stable and can survive for long periods of time in cool, moist conditions, infected animals shed huge numbers of infective oocysts (Fayer et al., 2010) and infection can pass through a group of susceptible hosts very quickly. The oocysts are also resistant to many disinfectants (Chalmers and Giles, 2010), there are no vaccines available to prevent the disease, and treatment options are limited and often rely on rehydration therapy. Good hygiene, such as preventing environmental contamination and proper disposal of contaminated material, are the most important ways to prevent infection (Radostits et al., 2008). Oocysts are resistant to most standard purification techniques, including filtration and chlorination. Reducing oocyst contamination of water sources are thought to offer the best protection from waterborne disease. Removal of the oocysts from drinking water by either boiling or by filtering the water through a filter with a pore size of <1 μm is also recommended for AIDS patients (Leav et al., 2003).

Many recommendations have been made for the prevention and control of infections in specific locations; such at hospitals, laboratories, day care centers, households, zoos and farms. These recommendations have basically involved managerial practices designed to minimize host contact with sources of infection and the use of different disinfection procedures to destroy infective oocysts (Haileyesus, 2010). Diarrheic calves should always be isolated from healthy calves during the course of the diarrhea, and for several days after recovery. Sick calves are commonly treated by the same person who feeds the healthy calves and great care must be taken to avoid mechanical transmission of infection. Calf-rearing houses should be vacated and cleaned out on a regular basis; an all-in all-out management system, with thorough cleaning and several weeks of drying between batches of calves, should be used (Radostits et al., 2006).

Prevention and control of cryptosporidiosis require continued efforts to interrupt the transmission of Cryptosporidium through water, food, and contact with infected persons and animals. Hygiene measures at any setting are essential. Particularly, continuous improvement and monitoring of respective run-off water sources and none treated water. Veterinarians could play a role in implementing hygiene measures to be adopted and regulated in the farm animal environment, but access of animals to surface and canal water realistically cannot be restricted. Prevention and control programs will have to be multifaceted. Land-use regulations, economic incentives, and educational efforts towards behavioral change may be necessary for the implementation and the success of long-term strategies (Yosra, 2014).

Vaccination has been proposed as a method to control cryptosporidiosis in animal populations (Jenkins, 2001; Riggs, 2002). Immunodominant Cryptosporidium antigens have been identified from natural infections and subunit vaccines have been prepared for the use in calves (Jenkins, 2001). However, it became obvious that using active and passive immunization approaches can reduce clinical signs but in most cases it could not eliminate or reduce the oocyst shedding. Nonspecific agents in milk, such as the epidermal growth factor have been shown to protect enterocytes from parasite-induced patho-physiological alterations (Buret et al., 2003). Immunophylaxis; Hyperimmune bovine colostrum can reduce the severity of diarrhea and the period of oocyst excretion in experimentally infected calves and lambs. Protection is not related to circulating levels of specific antibody but requires a high titer of C. parvum antibody in the gut lumen for prolonged periods (Radostits et al., 2006).

3. PUBLIC HEALTH IMPORTANCE OF CRYPTOSPORIDIUM

Waterborne contamination is a growing concern causing widespread disease outbreaks. Cryptosporidium now additionally is considered an important food-borne pathogen causing a disease of socioeconomic significance worldwide (Putignani and Menichella, 2010). Factors that have contributed to the emergence of cryptosporidiosis in animals include increased environmental contamination and trends in livestock production. In developing countries the impact of protozoan pathogens represents a major cause of gastrointestinal illness and is becoming of growing impact. Cryptosporidium accounts for up to 20% of all cases of childhood diarrhea in developing countries and is a potentially fatal complication of AIDS (Mosier and Oberst, 2000).
Current evidence indicates that the main reservoirs of zoonotic Cryptosporidium remain livestock, with the potential transmission of C. parvum although other species, and genotypes, have been reported in humans but only occasionally (Slapeta, 2013). Susceptibility to infection with other host adapted species and genotypes are largely governed by the immune status of the host (Slapeta, 2013).

Interestingly, although cattle have been repeatedly implicated as sources of water-borne outbreaks, the application of genotyping procedures to the contaminating isolate(s) has often incriminated human effluent as the source (Hunter and Thompson, 2005). The risk of infection appears greater within rural environments than within urban areas; presumably because of the increased opportunity for both direct and indirect transmission to occur in areas with poor sanitation and higher contact rates with domestic animal reservoirs of infection (Thompson and Smith, 2011).

The infection, however, is affected by the type of infecting isolates and the immune status of the host (Teunis et al., 2002). The incubation period ranges from 3-22 days with an average of one week (Checkley et al., 1998). Cryptosporidiosis more often affects children who are less than 3 years of age. In the developing countries it is a cause of death in immunocompetent infants who are less than 2 years of age (Xiao et al., 2001). The main clinical symptoms are a self limiting gastrointestinal illness, abdominal cramps and nausea, fever, vomiting, headache and growth retardation as well as other asymptomatic infections (Checkley et al., 1998). An infected patient can excrete more than 10^5 oocysts/g of faeces (McLauchlin et al., 1999). In immunocompressed patients cryptosporidiosis causes chronic, fulminant, transient or relapsing diarrhea which has even been associated with mortality (Manabe et al., 1998). The infection may spread throughout the alimentary canals and other mucosal surfaces, including the stomach and the biliary, the urinary or the respiratory tracts (Clemente et al., 2000; Megremis et al., 2004).

The economic impact of cryptosporidiosis, stemming from lost productivity, is enormous. Cryptosporidium infection in livestock may cause important economic impact to farmers because of its high morbidity and sometimes mortality rates among farm animals. Cryptosporidiosis, especially in young animals, can cause severe illness or death, resulting in decreased performance and production loss and results in financial loss to the producers from both extra care and supportive therapy needed and the death of production animals (Xiao et al., 2004). It also economic losses are short-term due to treatment costs of the diarrhea and longer term due to significant morbidity, impairment of growth, reduced weight gain and increased mortality in diseased animals (McDonald, 2000).

4. Cryptosporidium Infection in Ethiopia

The prevalence of cryptosporidiosis in Ethiopia is variable in different geographic regions, for example, there is higher prevalence of infection in the Afar region due to the low per capital coverage of clean potable drinking water supply and the intense association of the pastoralist population with domestic animals in comparison with Bishoftu, which is a modern urban center with potable water and limited contact with domestic animals. Other investigators have also reported that the prevalence of cryptosporidium species varies in different regions of the world and that species variability could occur in different geographic regions within a country (McLauchn et al., 2000).

Cryptosporidium is now becoming a common opportunistic intestinal parasite in Ethiopia even though it is not diagnosed routinely. Reports from different parts of the country showed different prevalence rates of cryptosporidiosis. Recently a study conducted in Lege Dini, rural area in Dire-Dawa, showed the prevalence of cryptosporidiosis to be 12.2 % (Ayalew et al., 2008).

However, some of the diagnostic methods for specific intestinal parasites, especially for the newly emerging opportunistic intestinal parasites, were not available to most of Ethiopian health institutions (Hileeyesus, 2010).

The prevalence of many intestinal protozoa parasites has been reported to be associated with the amount of rain fall (Enriquez et al., 1997). Studies in Central America, South Africa, Kuwait and India have also revealed a high peak incidence of Cryptosporidiosis in the rainy seasons (Iqbal et al., 2001). The same report was observed in eastern Ethiopia. With regard to this condition, the two water sources, Ali-spring and Diga dam, are highly exposed to runoff in the rainy season. Diga dam,
especially, is totally changed into runoff water as a result of which the district water Resource Office is forced to close the dam and stops providing service to community during the rainy season. This shows that contamination of drinking water sources by runoff containing feces of infected humans and animals is an inevitable phenomenon (Ayalew, 2006).

Molecular epidemiological studies have indicated the proportion of *C. parvum* infections in humans is much higher in rural than in urban areas (Learmonth *et al*., 2004). This could be due to zoonotic transmission of *C. parvum* from animals which are more prevalent in rural areas than urban. However, since the majority of study participants with Cryptosporidiosis in different studies were live in urban area and had limited contact with domestic animals, drinking water which usually is drawn from rural sources have been contaminated with cattle feasces could serve as the source of infection to urban peoples (Fikrie *et al*., 2008). It’s also reported that large herds may have a heavier pathogen load because of increased density of animals that favors infection of great number of calves, which in turn, contaminate their surrounding environment (Radostits *et al*., 2008).

5. **CONCLUSION AND RECOMMENDATION**

Cryptosporidiosis is a worldwide zoonotic parasitic disease that infects wide variety of animals and humans while infected animals and humans shed a very high number of oocysts. Its transmission occurs through direct or indirect contact with feces of these shedders. Outbreaks illustrate the person-to-person spread in institutions; animal contact during farm visits and contact with recreational waters, swimming pool visits, municipal drinking water and food are also different routes of transmission. Fatal diarrhea with malabsorption and dehydration occurs in young and immune compromised hosts. It has been reported that Cryptosporidiosis is highly prevalent in Ethiopia while documents on epidemiology and public health importance of it are scarce. Cryptosporidium are very resistant to adverse environmental factors and can survive for several months without losing its infectivity. To date, there is no effective therapeutic agent for Cryptosporidium infection but following adequate management and hygienic practices are paramount importance in the control and prevention of the disease. Based on the above conclusion the following recommendations are forwarded:

- Better management practices like stream-bank fencing, use all-in, all-out management system, isolate infected animals, cleaning and disinfection activities to limit environmental contamination with fecal matter and use protective materials when handling animals should be implemented.
- Awareness creation and extension service should be provided including healthy education to the farmers and other attendants.
- Swimming and direct drinking from lakes, streams and rivers should be avoided.
- Water should be pasteurized or boiled before consumption.
- Further studies are needed for effective treatment and implementation of sound prevention and control measures.
